Executive summary

Objectives
The purpose of this project is to obtain, analyse, and report on the current medical evidence relating to the risks and manifestations of pregnancy that may relate to aviation safety, and that may result in reduced functional capacity, incapacitation, or unsafe behaviour.

Review outcomes
Outcomes of interest were the prevalence and manifestation of the following conditions in pregnancy:

1. Overall symptoms and indications for sick leave
2. Pregnancy complications
3. Fatigue and sleep problems
4. Nausea and vomiting
5. Pelvic and back pain
6. Headache and migraine
7. Urinary and bowel problems
8. Vaginal bleeding
9. Miscarriage
10. Ectopic pregnancy
11. Venous thrombosis
12. Gestational hypertension, pre-eclampsia and eclampsia
13. Preterm birth
14. Cognitive disorders
15. Mental health disorders
16. Girth and mobility problems

Methods
We included studies of the incidence of common effects and complications of pregnancy. Preferred study designs were systematic reviews of population-based studies, and population-based cohort and cross-sectional studies.

The search included seven online databases, the references lists of articles retrieved, and use of online citation-linking tools. We selected relevant studies and extracted data on study characteristics and relevant findings. (See Appendix 1: Methods; Appendix 2: Table of included studies.)

Key findings are summarised in the text and table below (pp. 4-9). A description of the included studies and detailed findings for each review outcome are reported in the Results section (pp. 10-38).

Description of studies
We included 74 studies. They comprised 13 systematic reviews, 42 cohort studies, 16 cross-sectional surveys, one case-control study, one case report and one narrative review. Seventy-one of the studies were at low or moderate risk of bias.
Key findings

- Common symptoms of early pregnancy include (in order of prevalence), exhaustion, morning sickness, back pain and constipation. Headache is also commonly reported, but this may be due partly to high prevalence in the general population rather than the effects of pregnancy. Nearly 20% of women report often having three or more of these symptoms. Average quality of life scores are significantly below population norms, particularly in the areas of vitality and physical function.

- Based on Norwegian data, about 75% of women require sick leave during pregnancy, with absence rates increasing from 29% in the first trimester to 63% in the third. The most common indications for sick leave are fatigue or sleep problems and pelvic girdle pain. These are contributing factors for nearly half of women taking leave. For most indications the duration of sick leave ranges from 8 to 16 weeks, and 31% of women are on sick leave for at least 10% of their scheduled working time. In Sweden one in three women are treated in hospital at some point in their pregnancy.

- Over 36% of healthy New Zealand and Australian women experience a significant complication during their first pregnancy, such as high blood pressure, preterm delivery or a baby that is small for gestational age. Being in paid employment at 15 weeks' gestation is associated with reduced risk of such a complication. There is no good evidence as to whether the prevalence of pregnancy complications differs in any respect between airline pilots and other women.

- Nearly 40% of US women report poor sleep quality at 14 weeks' gestation, and symptoms tend to worsen over time, mainly due to discomfort. In both early and late pregnancy, one third of women report excessive daytime sleepiness, and over 40% of US and NZ women report that they regularly nap during the day in late pregnancy.

- Up to 80% of pregnant women experience nausea or vomiting, which is rated as comparable in severity to moderately nausea-producing cancer chemotherapy. Symptoms are usually limited to the first trimester, but persist for up to 22 weeks in about 10% of cases. Up to one third of pregnant women require sick leave for this indication (usually two to three weeks). Among Australian women with nausea and vomiting in early pregnancy, 4% resigned, 28% adapted their work hours to accommodate their symptoms and 65% reported that it reduced their attentiveness at work.

- Nearly 5% of pregnant women have hyperemesis gravidarum, defined as repeated vomiting in early pregnancy requiring inpatient admission, requiring day stay with IV fluids or nasogastric feeding, or causing loss of over 5% of booking weight. About 2% of pregnant women are hospitalised for hyperemesis gravidarum.

- Lower back or pelvic pain affects about 40% of pregnant women in the first trimester and is even more common in the second and third trimesters. Increased risk of back pain correlates with the need to twist or
bend frequently or to lift hands above shoulder level. Increased risk of pelvic pain correlates with working bent forward. Due to severe pelvic pain nine per cent of Swedish women gave up work during pregnancy and a similar proportion of Norwegian women reported having great difficulty with housework. Women rated pelvic girdle and lower back pain (at its worst) as similar to the worst pain experienced during delivery. Among Norwegian women with pelvic girdle pain, 16% required crutches during pregnancy.

- Headaches and migraine are usually less frequent and less severe in pregnancy than in non-pregnant women. Moreover among women with a history of migraine, attacks are usually less intense and of shorter duration.
- During pregnancy urinary frequency occurs in most women and urinary stress incontinence occurs in 30-45%. Symptoms tend to worsen as pregnancy progresses. However fewer than 3% of pregnant women with urinary incontinence report that it restricts their activities, and only about 1% find it a real problem.
- With regard to bowel symptoms, 13% of women reported that during pregnancy they experienced faecal urgency or incontinence (of flatus or stool).
- At least 20% of pregnant women have vaginal bleeding in the first trimester of pregnancy and up to 6% have bleeding in the second trimester. In about 10% of cases (in either trimester) the bleeding is heavy, and in about 5% of cases it is associated with moderate or severe pain. About 14% of women with first trimester bleeding and 28% of those with second trimester bleeding are admitted to hospital.
- Based on UK data, about 12% of known pregnancies end in clinically-confirmed miscarriage, and in about two thirds of cases women are admitted to hospital and undergo evacuation of the uterus. Nearly all miscarriages occur in the first trimester. In a Hong Kong study, although psychological morbidity decreased over one-year follow-up, 11% of women were still distressed a year after miscarriage. Evidence suggests that the prevalence of miscarriage in female flight crew does not differ from rates in other women.
- Ectopic pregnancy occurs in 1.5% to 2% of pregnancies, most commonly at around 7 weeks’ gestation. The most common symptoms are abdominal or pelvic pain, amenorrhea or vaginal bleeding. Suspected ectopic pregnancy requires urgent medical assessment and (if confirmed) may necessitate immediate surgery or medical treatment.
- There is wide variation in reported incidence rates for venous thrombosis in pregnant women, with estimates ranging from 5 to 20 per 10,000 pregnancies. Although antenatal venous thrombosis is a relatively rare event, it is a major cause of preventable maternal death. Management usually involves treatment until the end of the postpartum phase with anticoagulant injections once or twice daily.
Pre-eclampsia occurs in about 3-4% of pregnancies. It is more prevalent in first pregnancies, and occurs in over 5% of healthy nulliparous women. Pre-eclampsia is a complex, progressive and unpredictable disease with a major functional impact, usually requiring hospital admission. Eclampsia is very rare, occurring in about 0.1% of deliveries, but it is a leading cause of preventable maternal death.

Approximately 7% of babies in New Zealand are born preterm (before 37 weeks’ gestation). The rate of preterm birth among healthy women in their first pregnancy is nearly 5%, with twice the risk in smokers.

Case-control studies have suggested that pregnancy significantly impairs memory function and/or visuo-spatial ability, though the effects are subtle. However, the only good quality evidence available (from a prospective cohort study) suggests that pregnancy does not impair memory but that there may be a temporary decline in cognitive speed in the second half of pregnancy.

The prevalence of common mental disorders in pregnant women is comparable with (or lower than) rates in non-pregnant women. The symptoms and course of mental disorders is also similar in pregnant and non-pregnant women. However, the functional impact of such disorders can be especially severe in pregnancy, and anxiety or depression were responsible for longer sick leave (20 weeks) than any other health problem in antenatal women.

No evidence was found on the effects of increasing girth and potential mobility problems in pregnancy associated with this. The following comment appears on an aviation website (AvWeb); *Interestingly, the airlines do not restrict obese pilots from flying, and their stomachs can be more prominent than a pregnant woman’s at term.*

Conclusions

No direct evidence was found on the risks and manifestations of pregnancy in relation to aviation safety. However there was reliable evidence on the prevalence of the most common pregnancy-related conditions among the general female population of various westernised countries. There was limited evidence on the likely occupational effects of such conditions.

It seems reasonable to extrapolate the findings of the current evidence review to female aviators in New Zealand. Risks seem unlikely to be higher in this group than in the included studies, as recent evidence suggests that pilots (at least male pilots) in New Zealand are healthier than the general population in most respects.1

</table>
| Nausea and Vomiting | *First trimester: 80% of UK women have nausea or vomiting, with symptoms peaking at 9 weeks. 6*  
*Second trimester: 9% of UK women have ongoing nausea or vomiting at 16 weeks. 6* | 23% of pregnant Norwegian women require sick leave for nausea and vomiting (including HG), for a median duration of 16 weeks. 3*                                                                                     |
| Hyperemesis Gravidarum (HG) | *First trimester: 4.8% of women in the SCOPE study had HG. 7*  
*Second trimester: <1% of women in the SCOPE study had ongoing HG at 15 weeks. 7* | 2.1% of women in the SCOPE study required hospitalisation for HG. 7*  
Requirement for sick leave in all three trimesters is strongly associated with HG. 3*                                                                                                                        |
| Pelvic or lower back pain | *First trimester: 40% of Swedish women had back pain by 12 weeks. Worst pain in previous week was rated at 4/10 on VAS scale. Rates included women (20-22%) who had back problems before pregnancy. 8, 9*  
*Second trimester: In the Swedish cohort, prevalence of back pain increased steadily in the second trimester, with a sharp increase in weeks 18-22. Rates levelled off at about 63% of women by week 24. 9*  
*Third trimester: The prevalence remained stable: 63% of Swedish women had back pain at 36 weeks. Worst pain in the previous week was rated at 6.5/10 on VAS scale. 9* | 18% of pregnant Norwegian women require sick leave for lower back pain and 32% require sick leave for pelvic girdle pain. Median duration of leave is 10-12 weeks. 3*  
(Some women may be in both groups)                                                                                                                                                                                      |
| Headache and migraine | Although headaches are reported to be common in early pregnancy it is more common for headaches and migraine to stop during pregnancy than for them to start. 10, 11  
Headaches and migraine tend to become less common with increasing gestation and migraines become shorter and less intense. 10 |                                                                                                                                                                                                                      |
| Urinary and bowel problems | First trimester: 13-19% of women report urinary incontinence.\textsuperscript{12}  
Second trimester: About 19% of women report urinary incontinence.\textsuperscript{12}  
Third trimester: 30-38% of women report urinary incontinence.\textsuperscript{12}  
Throughout pregnancy: Most urinary continence is stress incontinence. About 81% of women report urinary frequency in pregnancy.\textsuperscript{13}  
13% of women report faecal urgency or incontinence (of faeces or flatus) during pregnancy.\textsuperscript{13}  
Fewer than 3% of pregnant women with urinary incontinence report that it restricts their activities.\textsuperscript{13}  
Only about 1% of pregnant women report that incontinence is "a hygienic or social problem".\textsuperscript{14} | Fewer than 3% of pregnant women with urinary incontinence report that it restricts their activities.\textsuperscript{13}  
Only about 1% of pregnant women report that incontinence is "a hygienic or social problem".\textsuperscript{14} |
|---|---|---|
| Vaginal bleeding | First trimester: 19% of women in the SCOPE study had vaginal spotting or bleeding in the first trimester.\textsuperscript{15*}  
Second trimester: 6% of women in the SCOPE study had vaginal spotting or bleeding at 13-20 weeks.\textsuperscript{15*}  
Less than 1% of women had new onset bleeding at 16-20 weeks.\textsuperscript{15*}  
Both trimesters: 10% of women with bleeding had one or more episodes of heavy bleeding.\textsuperscript{15*} | Among women with bleeding before 20 weeks, about half miscarry.\textsuperscript{16*} |
| Miscarriage | Before 20 weeks: In a UK primary care setting, about 12% of clinically confirmed pregnancies end in miscarriage before 20 weeks.\textsuperscript{16*}  
Most miscarriages occur in the first trimester. Up to 7% occur in the second trimester.\textsuperscript{16*} | About two thirds of women who miscarry are admitted to hospital, where about 60% of them have evacuation of the uterus.\textsuperscript{16*} |
| Ectopic pregnancy | Nearly all ectopic pregnancies occur early in pregnancy, with mean onset at about 7 weeks (SD ±2.2).\textsuperscript{17}  
Ectopic pregnancy most commonly presents with abdominal pain, amenorrhoea or vaginal bleeding.\textsuperscript{18} | Ectopic pregnancy requires urgent assessment and treatment (surgical or medical).\textsuperscript{19} |
| Venous thrombosis (DVT or PE) | In a recent systematic review the best estimate of the overall incidence of antenatal VT is 118 per 100,000 person-years (0.1%).\textsuperscript{20}  
Most studies report higher risk with increasing gestation.\textsuperscript{20} | Pregnancy-related VT is a major cause of preventable maternal death, due to the risk of fatal pulmonary embolism.\textsuperscript{21} |

Results

Characteristics of included studies
74 studies were included, comprising 13 systematic reviews, 21 prospective cohort studies, 21 retrospective cohort studies (using registry data), 16 cross-sectional surveys, one case-control study, one case report and one narrative review. Some of the studies had multiple publications, including one (the SCOPE study) that contributed six relevant papers.

Forty-nine of the studies were clearly population based. Most of the other studies were clinic-based without a clear indication as to whether their clientele were representative of the general population. The majority of systematic reviews included a mixture of population-based and other studies.

The 61 primary studies were set in Australia (n=4), Canada (n=2), Denmark (n=4), Finland (n=3), France (n=1), Hong Kong (n=1), Italy (n=2), Norway (n=9), New Zealand (n=7), Spain (n=1), Sweden (n=6), the UK (n=10), and the USA (n=7). Four were international (two set in in New Zealand and Australia, one in New Zealand, Australia, the UK and Ireland, and one in the USA and Canada).

Seventeen of the studies were rated as at low risk of bias and 54 were rated as at moderate risk of bias. Common study limitations were potential selection bias, low participation rates, retrospective data collection, small samples, uncertain reliability of registry data and (for systematic reviews) failure to explore heterogeneity and suboptimal literature search. Studies at high risk of bias were excluded, with the exception of three studies, which were included because they related to pregnancy in an aviation context.
Findings for each review outcome

1. Overall symptoms and indications for sick leave

Evidence base

- An Australian population-based cross-sectional survey of the general health of nulliparous women in early pregnancy
- A Norwegian longitudinal population survey of indications for sick leave in pregnancy
- A Danish register-based study of sick leave taken by hospital employees during pregnancy
- A Norwegian population-based cohort study of absence from work and job adjustment in pregnancy
- Swedish National Public Health Reports of indications for absence from work

Prevalence of symptoms

General health

An Australian population-based study reported on the general health of nulliparous women in early pregnancy. Symptoms experienced “occasionally or often” were (in order of frequency) exhaustion (87%), morning sickness (64%), back pain (46%), constipation (44%) and severe headache or migraine (30%). Nineteen percent of women reported often experiencing three or more of these. The authors noted that the impact of common comorbidities was most pronounced for younger women, but was strongly evident for all women in the sample.

Evidence on functional impact

Impact on functional roles

In the Australian study SF-36 status was significantly below population norms for most SF-36 categories. The domains most affected were vitality and physical role. The authors commented as follows: “These findings highlight the significant impact of early pregnancy symptoms on women’s physical and mental health. Although the common pregnancy symptoms reported are often considered ‘minor discomforts of pregnancy’, these findings suggest that the cumulative effect of experiencing multiple symptoms lasting longer than a few weeks significantly compromises women’s health and well-being in early to mid pregnancy”.

Sick leave

In the Norwegian studies of sick leave taken during pregnancy, 75% of women took sick leave: 29% in the first trimester, 39% in the second and 63% in the third. Over one third of women took more than 15 days of sick leave between weeks 13 and 28. Absence levels were lower among women whose working conditions were adjusted to allow for pregnancy where (in the woman’s view) this was required.
Swedish public health reports noted that a third of women are treated in hospital at some point in their pregnancy. 32,33

The most common reasons for sick leave were fatigue or sleep problems (which were an indication for sick leave in 35% of women) and pelvic girdle pain (32%). These conditions were contributing factors in 45-49% of women who took leave. Other common indications for leave were nausea or vomiting, and lower back pain (a contributing factor for 23% and 18% of women respectively). Nine per cent of women required leave for pregnancy complications. 3*

For most indications the median duration of sick leave ranged from eight to 16 weeks. Anxiety or depression were responsible for the longest median duration of sick leave.

Being on sick leave in all three trimesters was strongly associated with hyperemesis, exercising less than weekly, chronic pain before or during pregnancy, and infertility treatment. 3*

**Summary**

Common symptoms in early pregnancy include (in order of prevalence), exhaustion, morning sickness, back pain, constipation and severe headache or migraine. Nearly 20% of women report often having three or more of these symptoms. On average, quality of life is significantly below population norms, particularly in the areas of vitality and physical function.

Several European studies have assessed the need for sick leave during pregnancy. About 75% of women required sick leave during pregnancy, with absence rates increasing from 29% in the first trimester to 63% in the third. The most common reasons for sick leave were fatigue or sleep problems and pelvic girdle pain, which were contributing factors in nearly half of women who took leave. For most indications the duration of sick leave ranged from 8 to 16 weeks, and 31% of women were on sick leave for at least 10% of their scheduled working time.

In Sweden a third of women are treated in hospital at some point in their pregnancy.
2. Complications of pregnancy

Evidence base

- A prospective international cohort study with a New Zealand cohort (SCOPE) which reported the overall likelihood of complications in pregnancy.
- New Zealand Ministry of Health reports on hospital-based maternity events in 2006 and 2007.
- A literature review of gestational complications associated with air travel.

Incidence of complications

The SCOPE study found that among healthy nulliparous women with a singleton pregnancy 61.3% had an uncomplicated pregnancy, defined as normotensive, delivering a live baby not small for gestational age after 37 weeks, and having no other significant complications of pregnancy. Nearly 39% (2176/5628) had a significant complication. However, in the New Zealand and Australian cohort the rate of complications was lower (36.5%) than in the UK and Irish cohorts (41.4%).

Complications were defined as follows:

- Gestational hypertension
- Pre-eclampsia
- Gestational proteinuria
- Gestational diabetes
- Antepartum haemorrhage, placenta praevia, or placenta accreta
- Placental abruption
- Chronic hypertension (mild, diagnosed in pregnancy)
- Renal tract complications (e.g. pyelonephritis)
- Gastrointestinal tract or hepatic complications
- Respiratory complications (e.g. pneumonia)
- Other obstetric complications (e.g. obstetric cholestasis)
- Other medical complications (e.g. venous thromboembolism)
- Maternal death during pregnancy
- Small for gestational age infant (<10th customised birthweight centile)
- Spontaneous preterm birth
- Other fetal problems (including severe neonatal morbidity
- Fetal anomalies
- Fetal death in utero or neonatal death
- Miscarriage or abortion

When women with an uncomplicated pregnancy were compared with those without, it appeared that there were a number of factors amenable to individual lifestyle change which would reduce the risk of complications. Beneficial factors included normalising maternal weight, increasing pre-pregnancy fruit intake, reducing blood pressure, stopping misuse of drugs and being in paid employment at 15 weeks’ gestation (per 8 hours increase in employment RR 1.02, 95% CI 1.01 to 1.04).
A literature review of pregnancy complications associated with air travel reported that there was insufficient evidence to reach any conclusions.\textsuperscript{36} The review was non-systematic and associated with a high risk of bias, but the authors’ conclusions (with respect to lack of evidence) appear justified.

\textbf{Evidence on functional impact}

About 17\% of New Zealand of inpatient hospital admissions and 7\% of antenatal day stay admissions are for excessive vomiting; over 10\% of inpatient hospital admissions and nearly 8\% of antenatal day stay admissions are for gestational hypertension (with or without proteinuria); nearly 13\% of inpatient hospital admissions and 12\% of antenatal day stay admissions are for haemorrhage; and about 7-8\% of inpatient hospital admissions and 4\% of antenatal day stay admissions are for genitourinary infection. The mean duration of inpatient admission for these indications ranges from one to three days.\textsuperscript{34,35}

A further 28\% of New Zealand antenatal day stay admissions and 25\% of inpatient hospital admissions are for other (unspecified) maternal diseases complicating pregnancy. The mean duration of inpatient admission for this indication is two days.\textsuperscript{34,35}

\textbf{Summary of evidence}

Among healthy nulliparous women with a singleton pregnancy, over 60\% are likely to have an uncomplicated pregnancy, defined as normotensive, delivering a live baby not small for gestational age after 37 weeks, and having no other significant complications of pregnancy (as defined above). Over 36\% are likely to experience a significant complication. Being in paid employment at 15 weeks’ gestation has been identified as a factor associated with reduced risk of complications.

Complications of pregnancy may require hospital admission or same-day admission to an antenatal unit. The duration of inpatient stay for the most common complications is usually 1-3 days.

There is no evidence as to whether the prevalence of pregnancy complications differs in any respect between airline pilots and other women.
3. Fatigue and sleep problems

Evidence base

- Two population-based surveys of pregnancy-related morbidity in Australia and pregnancy-related sick-leave in Norway.*
- A cross-sectional survey of sleep problems in randomly-selected women booked to deliver at an NZ maternity unit.

Prevalence of fatigue and sleep problems

Exhaustion was the most common symptom in early pregnancy, experienced by 87% of Australian women “occasionally or often”. 11

The US study compared sleep disturbances at about 14 and about 30 weeks’ gestation. Poor sleep quality was reported by 39% of women at 14 weeks and 54% at 30 weeks. Other sleep-related problems that increased during pregnancy included insomnia (38% at 14 weeks and 54% at 30 weeks), short sleep duration (26% and 40% respectively) and restless legs syndrome (18% and 31% respectively). 4

The NZ study compared self-reported sleep duration and quality at 36 weeks’ gestation with (retrospectively recalled) pre-pregnancy values. Women reported deterioration in sleep quality, which was rated as fairly bad or very bad by 4% prior to pregnancy and by 38% in the previous week. The mean duration of sleep was 8.1 hours pre-pregnancy versus 7.5 hours in the previous week. Women reported that the main cause of sleeping problems was discomfort.

Evidence on functional impact

Fatigue or sleep problems were the most common indication for sick leave during pregnancy in the Norwegian study, and such problems were cited as a factor in 49% of sick leave taken. The median length of sick leave for this indication was 8 weeks.

Daytime fatigue was reported by 33% of NZ women in late pregnancy (versus 4% pre-pregnancy), and 41% regularly napped during the day (versus 5% pre-pregnancy). Similarly, excessive daytime sleepiness was reported by nearly 33% of US women at 14 weeks gestation and by 38% at 30 weeks.

Summary of evidence

Fatigue and sleep problems are the most frequently-reported symptom in early pregnancy, and are the most common indication for sick leave during pregnancy. Poor sleep quality is common in the first trimester (reported by 39% of US women at 14 weeks) and appears to get worse during pregnancy, mainly due to discomfort.

Over one third of women reported excessive daytime sleepiness in the first trimester and also in the third trimester. Over 40% of women in both early and late pregnancy reported that they regularly napped during the day.
4. Nausea and vomiting

Evidence base:
- A Canadian systematic review of NVP incidence rates\(^\text{37}\)
- An Australian systematic review of 38 studies of the impact of NVP\(^\text{38}\)
- A prospective study of NVP in UK primary care setting\(^6\*)
- A prospective study of NVP in Canadian tertiary care setting\(^39\*) (included in Einarson 2013 \(^\text{37}\))
- Two population-based surveys of pregnancy-related morbidity\(^11\) and pregnancy-related sick-leave\(^3\*)
- An Australian cross-sectional survey of the impact of nausea and vomiting \(^40\) (included in Wood 2013 SR\(^\text{38}\))
- A prospective international population-based cohort study with an NZ cohort (SCOPE), which reported the incidence of hyperemesis gravidarum \(^7\*)
- New Zealand Ministry of Health reports on hospital-based maternity events in 2006 and 2007 \(^34,35\)

Prevalence of nausea and vomiting

Nausea and vomiting
In an urban UK primary care setting, 52% of women had both nausea and vomiting during pregnancy, and a further 28% had nausea only.\(^6\*) Onset was usually at 5-6 weeks, peaking at 9 weeks. Symptoms often stopped abruptly at about 12 weeks, but 9% of women had ongoing symptoms at 16 weeks and beyond. Nausea most commonly occurred between 6 am and midday, but could occur at any time of day.

A prospective Canadian study\(^39\*) reported very similar findings: 74% of women had nausea during pregnancy, and half also had vomiting. The mean time of onset was 5.7 weeks’ gestation. Nausea resolved in 50% of cases by 14 weeks and in 90% by 22 weeks. It usually lasted throughout the day. Nausea ratings were rarely extreme, but were comparable in severity to those reported in a study of moderately nausea-producing cancer chemotherapy.

A recent systematic review\(^37\) reported widely varying rates of nausea and vomiting in pregnancy (55 studies, median rate in early pregnancy 69%, range 35% to 91%). Symptoms were reported as mild in 40% of cases, moderate in 46% and severe in 14%. The variation in rates may relate to differing definitions used by the included studies, and possibly also to ethnic differences in incidence. Rates were generally higher in Asian than in non-Asian countries.

In an Australian survey ‘morning sickness’ was the most common symptom in early pregnancy, experienced by 64% of women “occasionally or often”.\(^11\)

Hyperemesis gravidarum (HG)
In the SCOPE study\(^7\) HG was defined as repeated vomiting in early pregnancy requiring inpatient admission, day stay with IV fluids, nasogastric feeding (at home or in hospital) or vomiting associated with loss of over 5% of booking
weight. Among healthy nulliparous women the incidence of HG was 4.8%, and the incidence of severe HG requiring hospitalization was 2.1%. The mean incidence of HG in the Canadian systematic review was 1% (range 0.3% to 3.6%). The authors noted that there is no standard definition of HG but that hospitalization is often a requirement. Use of a wider definition of HG in the SCOPE study may account for the discrepancy in findings between the SCOPE study and the systematic review.

**Evidence on functional impact**

Among UK women in paid employment, 35% required time off due to nausea or vomiting. Mean time off was 62 hours. The likelihood of taking time off correlated with the severity of symptoms. NVP was an indication for sick leave in 23% of antenatal women in a Norwegian survey, and was the third most common indication for sick leave during pregnancy. Median duration of leave for this indication was 16 weeks.

Hyperemesis gravidarum is strongly predictive of being on sick leave in all trimesters and 2.1% of pregnant women require hospitalization for HG.

A systematic review of 38 studies assessed the impact of NVP on quality of life, including the ability to maintain professional commitments. It included an Australian study of 593 volunteers with nausea and vomiting in early pregnancy, in which over half the participants were in paid employment. In the early weeks of pregnancy, 14 women (4%) resigned from work, 95 women (28%) made changes to their work schedule, coming in later or leaving earlier, and 221 women (65%) thought they were less attentive at work. In this study SF-36 scores were lower on all dimensions than in healthy non-pregnant controls, especially for energy and physical functioning; scores for women in early pregnancy were comparable to published data for chronic illness.

Another prospective study administered questionnaires to 4041 pregnant women in Sweden. Women who took sick leave due to NVP took on average 13 days of leave, comprising 28% of all sick leave taken up to week 28. Other studies in the review reported a decline in work productivity among women with NVP, especially those with severe symptoms.

About 17% of New Zealand antenatal inpatient hospital admissions and 7% of daystay admissions are for excessive vomiting.

**Summary of evidence**

Up to 80% of pregnant women experience nausea or vomiting. It is usually limited to the first trimester, but persists for up to 22 weeks in about 10% of cases. Women’s’ ratings of nausea in pregnancy suggest that it is comparable in severity to moderately nausea-producing cancer chemotherapy.

About 23-35% of pregnant women require time off work (usually two to three weeks) due to nausea and vomiting. Among women with nausea and vomiting in early pregnancy, 4% resign, 28% adapt their work hours to accommodate their symptoms and 65%
report that it reduces their attentiveness at work. Quality of life scores for women in early pregnancy with nausea and vomiting are comparable to scores in people with chronic illness. Nearly 5% of women have hyperemesis gravidarum, defined as repeated vomiting in early pregnancy requiring inpatient admission, day stay with IV fluids, nasogastric feeding (at home or in hospital) or vomiting causing a loss of over 5% of booking weight. Women with HG often require sick leave in all three trimesters. About 2% of women have HG severe enough to require hospitalisation.
5. Pelvic and back pain

Evidence base

- A systematic review of pelvic girdle pain in pregnancy (in a guideline on pelvic girdle pain). It included four prospective studies. 8, 43-45
- A prospective Swedish population-based cohort study of back pain in pregnancy 9*
- A cross sectional Swedish population-based survey of pelvic girdle and lumbar pain 46*
- A population-based longitudinal survey of pregnancy-related sick-leave 3*
- Five population-based cross-sectional surveys of pelvic and/or lower back pain in pregnancy, conducted in Spain 47, Norway 48-50 and Sweden 51
- A cross-sectional analysis of baseline data from an Australian prospective cohort study of pregnancy-related morbidity 11

Prevalence of pelvic and back pain

Most studies reported high rates of pelvic and/or back pain during pregnancy, though estimates varied widely.

Pelvic girdle pain

Pelvic girdle pain is a specific form of low back pain, which occurs separately or in conjunction with other types of back pain. 50 The systematic review 42 estimated a point prevalence of pelvic girdle pain of about 20%. However there was variation between the four included studies: two 8, 43 found that 19-20% of women had pelvic girdle pain at 30-33 weeks, while the other two reported rates ‘in pregnancy’ of 14% 44 and 49%. 45

Any type of back pain

First trimester:

The Swedish cohort study 9* reported that 40.5% of women had any type of back pain in early pregnancy (before week 12), but that only 19.5% had new onset pain, as 21.5% of women had back pain before pregnancy. The mean score for the worst pain in the previous week was rated at 4/10 on a VAS scale.

Similarly, Ostgaard et al 8 noted that prevalence rates of back pain in pregnancy were influenced by the large number of women (22%) who already had ongoing pain before they became pregnant.

In an Australian study 11 ‘back pain’ was the third most common symptom in early pregnancy, experienced by 46% of women “occasionally or often”.

Second trimester

The Swedish cohort study 9* reported that there was a steady increase in all types of back pain from early pregnancy up to week 18. The incidence increased sharply from weeks 18-22 then levelled off. Prevalence at week 24 was 63.1%.

The Swedish cross-sectional study 46* reported that 62% of women had pelvic girdle or lumbar pain at 12-18 weeks, among whom over half had pelvic girdle pain, 29% had lumbar pain and 29% had both. In the Norwegian retrospective
cohort study,\textsuperscript{49} 23\% of women had moderate or severe pelvic or lower back pain at 5 months’ gestation.

\textit{Third trimester}

The Swedish cohort study\textsuperscript{9*} reported that 63.3\% of women had back pain (of any type) at 36 weeks’ gestation, among whom 16\% had pain pre-dating pregnancy. The mean score for the worst pain in the previous week was rated at 6.5/10 on a VAS scale.

A Spanish study\textsuperscript{47} reported that 71\% of women had lower back pain and 65\% had pelvic girdle pain at a median of 35 weeks’ gestation (range 31-35). By the end of pregnancy (at 9 months) about 42\% of women had moderate or severe pelvic and/or lower back pain in the Norwegian retrospective cohort study.\textsuperscript{49}

\textit{Throughout pregnancy (no specific trimester)}

Other studies reported rates of pelvic or back pain occurring at any stage of pregnancy. Robinson et al\textsuperscript{50} reported that 46\% of women had experienced pelvic girdle pain in their most recent pregnancy, while Endresen et al\textsuperscript{48} reported that 49\% of postpartum women had either pelvic or back pain or both during pregnancy. In the Swedish survey\textsuperscript{51} 72\% of women had lower back or pelvic pain (most commonly both), which started at a mean of 22 weeks’ gestation (range 1-39 weeks).

The Swedish cohort study\textsuperscript{9*} noted that back pain was usually short term and that long-term pain was rare. Pain intensity increased over pregnancy.

\textit{Evidence on functional impact}

Studies used a variety of measures to assess the functional impact of pelvic and back pain, including pain scores,\textsuperscript{9,46,49} disability scores,\textsuperscript{9,46,49} need for treatment,\textsuperscript{49} need for crutches,\textsuperscript{50} waking at night,\textsuperscript{50} difficulty with housework or with occupation\textsuperscript{45,48} and requirement for sick leave.\textsuperscript{3} Their findings varied widely.

Mogren et al\textsuperscript{51} reported that the worst back or pelvic pain experienced during pregnancy (mean pain score for worst pain 5.8, SD 2.2) was comparable with the worst pain during delivery (mean pain score for worst pain 5.4, SD 3.8).

Kristiannson et al\textsuperscript{9*} noted that the quartile with the worst back pain had difficulty with normal activities, such as walking up or down stairs, leaning over a sink, running, heavy work or lifting. Gutke et al\textsuperscript{46*} found that 15\% of women with pelvic girdle or lumbar pain at 12-18 weeks were not functionally affected. Most of the other women in this study reported only minimal disability and only 6\% reported moderate disability (Oswestry Disability Index >40\%). A third study\textsuperscript{49} which assessed functional impairment related to pelvic or lower back pain reported that among women with moderate to severe pain (57\% of the total sample), the mean score Oswestry disability index score indicated moderate disability. In this study 27\% of women received treatment for lower back or pelvic pain during pregnancy.

Waking up at night with pelvic girdle pain (PGP) was reported by 15\% of women in the Norwegian survey.\textsuperscript{50} This comprised 33\% of women with PGP. In this
study 7% of pregnant women (16% of those with PGP) required crutches in their most recent pregnancy as a result of PGP.

Another Norwegian study\(^4\) reported that 9% of women had serious difficulty with housework due to pelvic pain and that among women in paid employment the risk of pelvic pain was increased by working with the body bent forward. The risk of lower back pain was increased by occupations requiring frequent twisting or bending, or lifting the hands above shoulder height.

Ostgaard et al\(^8\) also reported occupational factors that increased the prevalence of back pain during pregnancy; these included physically heavy work, lifting, twisting, bending forward, poor work satisfaction, post-work fatigue, inability to take rest breaks and constrained working postures.

One of the studies in the systematic review\(^4\) reported that for 9% of women, the severity of pelvic pain necessitated giving up work.

Pelvic pain was the second most common indication for sick leave during pregnancy in the Norwegian study, and was an indication for sick leave in 32% of women. Median duration of leave for this indication was 10-12 weeks. Lower back pain was an indication for sick leave in 18% of women, for a median duration of 10 weeks.\(^3\) In another Norwegian study,\(^5\) 67% of all pregnant women were "sicklisted" during pregnancy, among whom 41% reported that the indication was PGP.

**Summary of evidence**

Pelvic and back pain are very common during pregnancy. This is partly because over 20% of women with back pain in early pregnancy already have back pain before they become pregnant.

Nearly half of pregnant women have lower back or pelvic pain occasionally or often in the first trimester and 50-72% have this type of pain in the second or third trimester.

Assessment of the functional impact of back pain varied widely, but nearly 60% of women in one study reported some functional impairment during pregnancy (such as more pain and difficulty with sitting, lifting and standing). Nearly 10% of women with pelvic pain reported a high degree of functional impairment, resulting in giving up work or having difficulty with housework.

Pelvic girdle pain was an indication for sick leave during pregnancy in 32% of women, median duration of leave being 10-12 weeks. The worst pain associated with pelvic girdle and lower back pain was rated as similar to pain during delivery. Among women with pelvic girdle pain, 16% reported that they required crutches during their most recent pregnancy.
6. Headaches and migraine

Evidence base

- Two population-based Norwegian studies of the prevalence of headaches and migraine in pregnancy, one prospective cohort study\(^5\) and one cross-sectional survey\(^1\)
- An Australian population-based cross-sectional survey of the general health of nulliparous women in early pregnancy\(^1\)

Prevalence of headaches and migraine

The Norwegian cross-sectional survey\(^1\) found that overall migraine and non-migrainous headache were less prevalent overall among nulliparous pregnant women than among non-pregnant women (One year prevalence: OR 0.5, 95% CI 0.4 to 0.7). The same trend was seen for multiparous pregnant women but the difference was not significant (OR 0.8, 95% CI 0.7 to 1.0). There was no difference in headache prevalence during the first and second trimester between pregnant and non-pregnant women, but headache was significantly less prevalent in the pregnant women in the third trimester than in non-pregnant women (OR 0.4, 95% CI 0.3 to 0.6). This applied to all pregnant women and to both migraine and non-migrainous headache.

Similarly, the prospective study noted a gradual decrease during pregnancy in the frequency of headaches and migraine in general.\(^5\)

The prospective study\(^5\) also found that more women changed during pregnancy from having headaches to not having headaches (248/1,618 = 15%) than the other way around (101/1,618 = 6%) (p< 0.001). Overall there was no significant difference in the prevalence of headaches and migraine (combined) between pregnant and pre-pregnant women. Among women who reported migraine, the intensity and duration of headaches was significantly reduced during pregnancy.

In the Australian survey,\(^1\) 30% of women reported having a severe headache or migraine during early pregnancy either occasionally or often.

Evidence on functional impact

The evidence suggests that for most women, pregnancy is not associated with increased headaches or migraine and that it is more likely to reduce their impact, especially in the second and third trimester.

Summary of evidence

Headaches and migraine are usually less frequent and less severe in pregnant women than in non-pregnant women, especially in the later stages of pregnancy and especially in nulliparous women. Moreover among women with a history of migraine, attacks are likely to be less intense and of shorter duration. However some women develop new symptoms in pregnancy, and an Australian survey reported that 30% of women experience severe headache or migraine ‘occasionally or often’ in early pregnancy.
7. Urinary and bowel problems

Evidence base

- A systematic review of studies of the prevalence of urinary incontinence in pregnancy \(^{12}\)
- A prospective Danish longitudinal study of urinary symptoms in pregnancy (and postpartum) \(^{14}\) (included in Sangsawang et al \(^{12}\))
- A prospective UK longitudinal study of urinary and faecal incontinence in pregnancy (and postpartum) \(^{13}\)
- An Australian population-based cross-sectional study on the general health of nulliparous women in early pregnancy \(^{11}\)
- New Zealand Ministry of Health reports on hospital-based maternity events in 2006 and 2007 \(^{34},^{35}\)

Prevalence of urinary and bowel problems

Urinary symptoms
A prospective UK study \(^{13}\) reported that among nulliparous women with a singleton pregnancy at a London hospital, 81% reported urinary frequency, 44% reported urinary incontinence, and 9.3% had urinary incontinence at least daily.

The systematic review \(^{12}\) found a wide disparity in estimates of the prevalence of urinary incontinence in pregnancy. Overall stress incontinence rates ranged from 19% to 60%, incontinence with urgency from 2% to 35% and mixed incontinence from 4% to 13%. Variation in rates appeared to relate partly to study setting. In most European and Australian studies, between 30% and 45% of women reported urinary incontinence at some stage during pregnancy, with higher rates in multiparous women.

The risk of urinary incontinence increased with gestational age, with a rate of 13% to 19% reported in the first trimester. The rate in the second trimester was 19.2 %, and in the third trimester was 30-37.5 %. \(^{12}\)

Bowel symptoms
The UK study \(^{13}\) reported that 9% of pregnant women experienced faecal urgency, 6% incontinence of flatus and nearly 1% incontinence of liquid stool. Thirteen per cent reported any urgency or incontinence of flatus or stool.

The Australian study \(^{11}\) reported that 44% of women experienced constipation occasionally or often in early pregnancy.

Evidence on functional impact
A Danish population-based study \(^{14}\) in the systematic review \(^{12}\) reported that the prevalence of urinary stress incontinence in pregnancy was 32%, but that the prevalence of such incontinence “causing a hygienic or social problem” (the definition used by the International Continence Society) was only 1%. The authors concluded that the psychosocial impact of symptoms is modest.

Among women in the UK study who had urinary incontinence, 10.2% wore
sanitary protection. Only 2.8% felt that the symptoms restricted their activities.

About 4% of New Zealand antenatal day stay admissions and 7-8% of inpatient hospital admissions were for genitourinary infection. The mean duration of inpatient admission for this indication was two days.\textsuperscript{35, 34}

**Summary**

During pregnancy urinary frequency occurs in most women. Urinary incontinence (usually stress incontinence) occurs in 30-45%. Rates of incontinence are higher in multiparous women and with increasing gestational age. Fewer than 3% of women with urinary incontinence in pregnancy report that it restricts their activities. Only about 1% of pregnant women find it problematic (‘a hygienic or social problem’).

Genitourinary infections are the fourth most common indication for antenatal hospital admission in New Zealand, responsible for about 8% of such admissions.

With regard to bowel symptoms, 44% of Australian women reported occasional or frequent constipation in early pregnancy, while in a UK study 13% of women reported that during pregnancy they experienced faecal urgency or incontinence (of flatus or stool).
8. Vaginal bleeding

Evidence base:

- A systematic review of abnormal bleeding in the second half of pregnancy
  - A prospective UK population-based primary care cohort study of bleeding early in pregnancy
  - Three prospective population-based cohort studies of first or second trimester bleeding reported by women with pregnancies ongoing at 20-28 weeks. They were set in Finland, Denmark and internationally (SCOPE study)
  - Two prospective cohort studies in US hospital settings, describing first or second trimester bleeding reported by women with pregnancies ongoing at 20-29 weeks
  - A retrospective hospital registry-based Australian study of bleeding occurring after 24 weeks’ gestation
  - Two New Zealand Ministry of Health reports on Hospital-based Maternity Events in 2006 and 2007

Prevalence of vaginal bleeding

Estimates of the incidence of bleeding in pregnancy vary according to the definition of bleeding and measures used. Most studies only included women with pregnancies ongoing at 20-29 weeks. These studies did not include women who miscarried prior to 20-29 weeks. Moreover data on early bleeding were subject to potential recall bias in most studies.

First trimester bleeding

In a recent international study with a New Zealand cohort 19% of nulliparous women had bleeding in the first trimester, including any event from spotting to heavy bleeding. Other studies using a similar definition of bleeding reported rates of 16%, 19% and 23%. All these studies only included women with ongoing pregnancy at 20-29 weeks.

In most cases first trimester bleeding consisted of a single episode of light spotting lasting from 1-3 days. However about 10% of women reported moderate to heavy bleeding. Onset of bleeding was most commonly at six to eight weeks’ gestation.

Second trimester bleeding

Vaginal bleeding was less common in the second trimester, with estimated rates ranging from 2% to 6%. Fewer than 1% of women had new-onset bleeding in weeks 16-20. A systematic review reported that the incidence of bleeding of unknown origin in the second half of pregnancy was 2%.

As in the first trimester, bleeding was moderate to heavy in about 10% of cases.

Bleeding in either first or second trimester

The only population-based study that has prospectively collected data on bleeding from conception onwards reported a bleeding rate of 21% in the first
20 weeks in a semirural UK primary health setting.\textsuperscript{16} It was unclear whether this study included spotting in the definition of bleeding.

Among women with bleeding, nearly two thirds reported that it was not associated with pain, while 31\% reported light pain. Pain was more common among women with heavy bleeding, of whom 50\%-54\% reported pain. Five percent of women with bleeding reported moderate or severe pain which lasted more than a day.\textsuperscript{55}*

\textit{Evidence on functional impact}

Among women with first trimester bleeding, about 14\% were admitted to hospital, usually for fewer than 7 days. Among women with second trimester bleeding, about 28\% were admitted to hospital for up to 13 days.\textsuperscript{55}*

Antepartum haemorrhage accounted for about 13\% of antenal hospital admissions and 12\% of same-day antenal admissions in NZ in 2006 and 2007. These figures include about 3\% of antenal admissions and 7\% of same-day admissions which were specifically reported as being in \textit{early} pregnancy. The average length of overnight stay was under 2 days.\textsuperscript{34,35}

\textit{Summary of evidence}

The evidence suggests that at least 20\% of pregnant women have vaginal bleeding in the first trimester of pregnancy and at least 5\% have bleeding in the second trimester.

Bleeding most commonly occurs around weeks 6-8, and often consists of a single episode of light bleeding or spotting, lasting for up to three days. In about 10\% of cases, vaginal bleeding is heavy. The bleeding is usually painless, but in about 5\% of cases it is associated with moderate or severe pain.

About 14\% of women with first trimester vaginal bleeding and 28\% of women with second trimester vaginal bleeding are admitted to hospital. This indication accounts for 12-13\% of day and inpatient antenal hospital admissions in New Zealand.

Bleeding rates are probably higher than reported in these studies, as most did not include women with vaginal bleeding related to miscarriage.
9. Miscarriage

Evidence base

- A systematic review of population-based cohort studies of miscarriage rates at up to 20 weeks gestation 59
- A prospective UK population-based primary care cohort study of miscarriage 16*
- Two prospective cohort studies of miscarriage rates in the general population, conducted in Sweden 60* and Denmark 61*
- Three cross-sectional surveys of miscarriage rates in the general population conducted in Finland 62, the UK 63 and New Zealand 64
- A retrospective cohort study of first-trimester miscarriage rates among Finnish flight attendants 65
- A retrospective analysis of baseline data from a multicentre US cohort study 66
- Two New Zealand Ministry of Health reports on miscarriages occurring in hospital in 2006 and 2007 34, 35
- A longitudinal hospital-based cohort study of psychological morbidity after miscarriage, conducted in Hong Kong 67
- A UK case-control study comparing miscarriage rates in female flight crew with those in female air-traffic controllers 68
- A UK cohort study of registry data, reporting the annual incapacitation rate of commercial pilots 69

Incidence of miscarriage

Miscarriage was defined in these studies as spontaneous pregnancy loss before 20-28 weeks. As with bleeding, reported incidence rates for miscarriage are likely to be underestimates. Studies noted the potential for confounding related to unsuspected pregnancy loss, early miscarriage for which women do not seek medical help or are not hospitalised 16, 61* and high rates of legal abortion. 60* The likely effect of such confounding is that miscarriage rates may be over 30% higher than official statistics suggest 16*

In most studies the miscarriage rate was between 11% and 13% of all pregnancies, 16, 60, 62, 63 though a systematic review reported estimates ranging across studies from 11% to 22%. 59 In one study 61* the self-reported miscarriage rate was 21%, but based on hospital registry data for the same cohort of women the rate was only 16%.

Most miscarriages occur in the first trimester: one study reported that 88% of miscarriages occurred at 6-14 weeks and about 7% of miscarriages at 16-18 weeks’ gestation (data were missing for 5%). 16* Two studies estimated the risk of miscarriage in the second trimester (up to 20-24 weeks) at 0.5% to <1%. 24, 66

A New-Zealand population-based study 64 reported that about one third of women have at least one miscarriage in their lifetime, at a conservative estimate. Other estimates were 25% (by age 39) in Sweden 60*, and 50% (by age 44) in Finland. 62
A study of first trimester miscarriage among flight attendants reported a rate of 12%. The UK case-control study of flight crew found that the risk of miscarriage among flight crew was similar to that of air-traffic controllers (OR 1.39, 95% CI 0.58 to 3.33 (adjusted for maternal age, BMI and smoking history)), suggesting that the risk of miscarriage is not increased by flight-crew related exposures.

Evidence on functional impact
In the UK primary care study, about two thirds of women who miscarried were admitted to hospital. About 63% of women who miscarried underwent evacuation of the uterus. In New Zealand rates of referral to hospital for miscarriage are around 5% per pregnancy for European and Asian women, and around 6-7% among Pacific and Maori women. These figures are not overall population rates, as they do not include miscarriages occurring elsewhere. The above-mentioned UK study estimated that at least a quarter of all known miscarriages are treated at home by general practitioners and not recorded in any published statistics.

A cohort study of psychological morbidity among women admitted to a Hong Kong Hospital for management of miscarriage found that although scores for distress and depression decreased over one-year follow-up, 11% of women were still distressed (compared to a control group) after 1 year.

A UK study reported the prevalence of incapacitations in commercial pilots in 2004. The cohort included 617 female pilots. The sole incapacitation among the female pilots was a spontaneous abortion at 22 weeks in a pilot who was already deemed temporarily unfit, due to pregnancy.

Summary of evidence
Between 11% and 22% of known pregnancies end in miscarriage (spontaneous pregnancy loss before 20-28 weeks). Data on early miscarriages are unreliable, partly due to the high proportion of miscarriages for which women do not seek medical help. Around 90% of miscarriages occur in the first trimester.

In New Zealand, rates of referral to hospital for miscarriage are about 5% for European and Asian women and 6-7% for Pacific and Maori women. Based on UK population data, about 12% of pregnancies end in clinically-confirmed miscarriage, and in about two thirds of cases women are admitted to hospital after miscarriage and undergo evacuation of the uterus.

A cohort study of women admitted to a Hong Kong Hospital for management of miscarriage found that although psychological morbidity decreased over one-year follow-up, 11% of women were still distressed one year later.

There is some evidence to suggest that the prevalence of miscarriage in female flight crew is similar to rates in other women.
10 Ectopic pregnancy

Evidence base
• Six retrospective population-based cohort studies set in Norway,\textsuperscript{70} Australia,\textsuperscript{71} France,\textsuperscript{72} the UK,\textsuperscript{73} Sweden,\textsuperscript{74} and Italy\textsuperscript{75}
• One large North American retrospective cohort study of women with ectopic pregnancy\textsuperscript{17}
• Two clinical guidelines\textsuperscript{18, 19}

Incidence of ectopic pregnancy
All the population-based cohort studies aimed to evaluate changes in the annual incidence of ectopic pregnancy over periods of 8-15 years. Older studies tended to report a declining rate,\textsuperscript{70, 71} while more recent studies reported stable or increasing rates.\textsuperscript{72, 73, 75} In the most recent year reported in each study (which ranged from 1995 to 2010), the rate of ectopic pregnancies per 10,000 women-years ranged from 5.1 to 10, and the rate per 1000 pregnancies or deliveries ranged from 6.3 to 16.

The population-based cohort studies did not report gestational age at presentation in their samples. However a large North American chart review\textsuperscript{17} described the characteristics of 693 consecutive ectopic pregnancies. The mean gestational age for diagnosis of unruptured ectopic pregnancy was 6.9 weeks (SD 1.9), and of ruptured ectopic pregnancy was 7.2 weeks (SD 2.2).\textsuperscript{17}

Evidence on functional impact
Clinical presentation of ectopic pregnancy ranges from a missed period or pelvic tenderness to (rarely) shock and collapse. The most common symptoms are abdominal or pelvic pain, amenorrhea or vaginal bleeding. Women with suspected ectopic pregnancy require immediate referral to an early pregnancy assessment unit or gynaecology clinic.\textsuperscript{18} Management usually involves laparotomy, operative laparoscopy or medical treatment.\textsuperscript{19}

Summary of evidence
Ectopic pregnancy occurs in about 1.5% to 2% of pregnancies. It usually presents in early pregnancy, most commonly at around 7 weeks' gestation. Clinical presentation varies but the most common symptoms are abdominal or pelvic pain, amenorrhea or vaginal bleeding. Suspected ectopic pregnancy requires urgent medical assessment and (if confirmed) may necessitate immediate surgery or medical treatment.
11. Venous thrombosis

Evidence base

- A systematic review of DVT rates in pregnancy
- A population-based retrospective cohort study of the incidence of VT in England, which was accompanied by a comparative systematic review of 21 other VT incidence studies
- A retrospective population-based cohort study of the incidence of VT in a US County over 30 years (included in Abdul Sultan 2013 SR)
- A population-based retrospective cohort study of the incidence of VT in Scotland
- A retrospective chart review of VT rates at two hospitals, one in New Zealand and one in Australia
- A literature review of gestational complications associated with air travel

Incidence of venous thrombosis

Venous thrombosis (VT) was defined in the included studies as deep vein thrombosis (DVT) or pulmonary embolism (PE) diagnosed using objective clinical criteria (need for anticoagulants, imaging tests) or by ICD-10 codes. All relevant studies were retrospective or cross-sectional analyses of data from national registries or hospital discharge databases.

The incidence of antenatal VT in England was estimated at 99 per 100,000 person-years in the primary study conducted by the authors of one of the systematic reviews. The rate in their accompanying meta-analysis ranged from 53 to 144 per 100,000 woman-years. The authors addressed heterogeneity by limiting analysis to post-2005 studies which conducted a form of case validation (n=4), a process which resulted in a pooled estimate of 118 per 100,000 years.

Other studies also reached widely varying estimates: the recent Scottish study estimated a rate of 136 per 100,000 deliveries, whereas the rate in a small New Zealand-Australian chart review was only 40 to 59 per 100,000 deliveries.

Most VT events were DVTs: in Heit et al the overall incidence of antenatal VT was 96 events per 100,000 years, of which 85 events were DVT and 11 were PE.

The two SRs reported increasing risk of VT with increasing gestation. One estimated incidence rates of VT at 46, 58 and 182 per 100,000 woman-years in the first, second and third trimesters respectively (though with wide variation between studies). The other reported that 22% of DVTs occur in the first trimester, 34% in the second and 48% in the third. In the small NZ/Australian study there was no difference between the rates in different trimesters, with 14, 7 and 10 events occurring in the first, second and third trimesters respectively.

The incidence of VT peaked around the time of delivery and was fivefold higher during delivery and the postpartum period than in the antenatal period. A similar trend was noted in the NZ study. Rates of VT in pregnancy and post-
partum were over four times greater than among non-pregnant women in the same population.\textsuperscript{77}

Although it is recognised that both air travel and pregnancy increase the risk of VT, there appears to be no evidence about their combined risk.\textsuperscript{36,79}

\textbf{Evidence on functional impact}

Pregnancy-related VT is a major cause of preventable maternal death (associated with fatal pulmonary embolism). Women diagnosed with antenatal VT are generally treated with short-acting anticoagulants given subcutaneously once or twice daily, and monitored with regular blood tests for the remainder of the pregnancy and post-partum period.\textsuperscript{21}

\textbf{Summary of evidence}

There is wide variation in estimated incidence rates for venous thrombosis (deep vein thrombosis (DT) and pulmonary embolism (PE)) among pregnant women. This may relate to differences in data sources, coding practices and in the use of different diagnostic tools, such as imaging.

Estimated rates of VT during pregnancy range from 50 to 200 per 100,000 pregnancies. Ninety per cent of antenatal VTS are DVT rather than PE.

Although VT is a rare event in pregnancy, it is a major cause of preventable maternal death and requires treatment until the end of the postpartum phase, usually by means of anticoagulant injections once or twice daily.
12. Pre-eclampsia and eclampsia

**Evidence base**

- A systematic review of worldwide incidence rates of pre-eclampsia and eclampsia 24*
- A prospective international cohort study with a New Zealand cohort (SCOPE) 22*
- A prospective population-based NZ cohort study of BP in pregnancy 80*
- An NZ population-based retrospective cohort study 81
- A retrospective NZ/Australian cohort study 82
- A retrospective population-based Norwegian cohort study 83
- New Zealand Ministry of Health reports on hospital-based maternity events in 2006 and 2007 34, 35
- A New Zealand Health Quality and Safety Commission report 84

Australian and New Zealand guidelines 23 use the following definitions for hypertensive disorders arising in pregnancy:

- Gestational hypertension: new onset hypertension at >20 weeks’ gestation, without proteinuria or other features of pre-eclampsia
- Pre-eclampsia: hypertension with proteinuria (or other organ involvement) at >20 weeks’ gestation
- Eclampsia: pregnancy-related seizures

**Incidence of pre-eclampsia**

The systematic review 24* estimated that in the Western Pacific area (Australia, Japan, Korea, New Zealand and Singapore) 3.9% of women giving birth have pre-eclampsia. However confidence intervals were very wide (95% uncertainty range 1.8 to 9.2). Eclampsia (pregnancy-related seizures) occurred in about 0.1% of deliveries.

The SCOPE study, an international population-based prospective cohort study with an NZ cohort 22* reported a 5.3% prevalence of pre-eclampsia in healthy nulliparous women, including 1.3% who had *pre-term* pre-eclampsia, defined as eclampsia resulting in delivery before 37 weeks. Pre-eclampsia developed at a mean of 36.9 (SD 3.3) weeks’ gestation.

A prospective population-based NZ cohort study of BP in pregnancy 80* reported a 3.2% rate of antenatal pre-eclampsia. Incidence of eclampsia was 0.05%. In addition 10.8% of participants had antenatal gestational hypertension (hypertension without proteinuria).

Retrospective registry-based cohort studies conducted in Australia and New Zealand 82, New Zealand only 81 and Norway 83 estimated pre-eclampsia rates at 3.3% to 4.2% per birth. Nearly 10% of women had *any* gestational hypertension 82.

The New-Zealand registry study 81 identified independent risk factors for preeclampsia which included Maori ethnicity (50% higher risk), and being overweight or obese. The risk was 50% lower in Chinese women.
**Evidence on functional impact**

The usual management of gestational hypertension is ongoing monitoring to facilitate early detection of pre-eclampsia or severe hypertension.\(^{23}\)

Preeclampsia is a progressive disorder that worsens as pregnancy continues. The standard management is close observation of mother and fetus until 37 completed weeks or until the onset of either maternal or fetal complications. This usually involves hospital admission.\(^{23}\)

As noted above, in about 1.3% of first pregnancies in the SCOPE study, pre-eclampsia was associated with delivery before 37 weeks’ gestation.\(^{22}\)

As also noted above, eclampsia is very rare, affecting only about 0.1% of deliveries. However it is a leading cause of preventable maternal death.\(^{84}\)

In New Zealand, nearly 8% of antenatal daystay admissions and over 10% of inpatient hospital admissions are for gestational hypertension (with or without proteinuria).\(^{34},^{35}\)

**Summary of evidence**

Pre-eclampsia occurs in about 3-4% of pregnancies overall. It is more prevalent in first pregnancies, and occurs in about 5.3% of healthy nulliparous women in their first pregnancy. About 1.3% of first pregnancies (in healthy women) result in delivery before 37 weeks’ gestation due to pre-term pre-eclampsia.

By definition pre-eclampsia does not occur before 20 weeks. Median gestation at time of diagnosis in the SCOPE study was 36.9 weeks.

Pre-eclampsia is a complex, progressive and unpredictable disease with a major functional impact, usually requiring hospital admission.

Eclampsia is very rare, occurring in about 0.1% of deliveries, but it is a leading cause of preventable maternal death.
13. **Pre-term birth**

Preterm birth is defined as birth before 37 weeks’ gestation.

**Evidence base:**

- A systematic review of 92 studies of pre-term birth rates worldwide[^85star]
- Two publications from a prospective international cohort study with a New Zealand cohort (SCOPE)[^25, 26star]
- A New Zealand Ministry of Health report, based on data from hospitals and lead maternity carers[^86]

**Incidence of pre-term birth**

The New Zealand Ministry of Health reported[^86] that in 2010 7.4% of all live born babies in New Zealand were born preterm. Rates varied by ethnicity and socioeconomic status. The systematic review[^85star] reported a rate of 6.4% in Australasia (Australia and New Zealand), for all preterm births.

The SCOPE study[^25star] reported that among healthy nulliparous Australian and New Zealand women (n=2535), the preterm birth rate was 4% in non-smokers and 10% in smokers. In the wider international study population (n=3234) the overall rate was 4.9%.

**Summary of evidence**

Approximately 7% of babies in New Zealand are born preterm (before 37 weeks’ gestation), with individual risk varying according to demographic and behavioural factors. The rate in healthy women in their first pregnancy is 4-5%, with twice the risk in smokers.

[^25]: Reference
[^26star]: Reference
14. Cognitive disorders

Evidence base
- A prospective Australian cohort study of cognition in pregnancy and motherhood
- A systematic review of 14 small case-control studies of the effects of pregnancy (and the post-partum) on memory
- A case-study of a pregnant pilot tested for mental rotation ability

Prevalence of cognitive disorders
The systematic review found that pregnant women (n=412) were significantly impaired on measures of short-term memory, working memory, free recall and delayed free recall, compared to non-pregnant controls (n=386). There was no significant difference between the groups in measures of recognition, implicit memory or subjective memory.

The Australian study recruited women prior to pregnancy and compared cognitive changes in women who subsequently became pregnant with changes in those who did not, using four measures of cognition (cognitive speed, working memory, immediate recall, delayed recall). Pregnant women were categorized into early and late pregnancy (pre 20 weeks and 20-40 weeks gestation, respectively). There was no difference between the groups for any measure except cognitive speed in the later stages of pregnancy; and the difference was no longer significant when all pregnant women were considered as a group. For this outcome, non-pregnant women recorded an improvement or stability between measures, whereas performance fell in pregnant women, with a significant difference between the groups. However the difference did not persist: there were no differences between non-pregnant women and mothers.

Evidence on functional impact
The authors of the systematic review concluded that “memory measures that place relatively high demands on executive cognitive control may be selectively disrupted in pregnancy”. However they noted that in all cases the effects were small and that “the observed impairment may be regarded as relatively subtle”.

The authors of the prospective cohort study stated that “Except in a brief period in later pregnancy, (our) findings challenge the common myth that women develop ‘placenta brain’”.

The authors of the case-study of mental rotation ability in a female pilot concluded that there was an effect of pregnancy on visuo-spatial ability that can last for some time after delivery. As no baseline (pre-pregnancy) measures were taken in this study and the pilot’s performance did not vary significantly between pregnancy, post-partum or one year after delivery, these conclusions appear unreliable.

Summary of evidence
The evidence of case-control studies suggests that pregnancy significantly impairs short-term memory, working memory, free recall and delayed free recall, though differences are relatively subtle.
However, the only evidence from a prospective well-controlled cohort study (which tested cognitive speed, working memory, immediate recall and delayed recall in early and late pregnancy) suggests that pregnancy does not affect memory. However there may be a temporary decline in cognitive speed in the second half of pregnancy.

A recent case-study suggested that mental rotation ability may be impaired in female pilots during pregnancy, but this evidence does not appear reliable.
15. Mental health disorders

Evidence base

- Three systematic reviews of depression rates with differing inclusion criteria but considerable overlap between studies
  - A study of US epidemiological survey data
  - A Norwegian population-based study of sick leave taken during pregnancy
  - A systematic review of studies of the prevalence of obsessive compulsive disorder in pregnancy

Prevalence of mental health disorders

All mental disorders
A cross-sectional studies of US epidemiological survey data from 2001-2 compared the prevalence of mental disorders in currently pregnant women compared to non-pregnant, non post-partum women. It assessed DSM-IV-diagnosed disorders including major depression, dysthymia, bipolar disorder, social phobia, specific phobia, generalized anxiety disorder, panic disorder, alcohol abuse or dependence and drug abuse or dependence. Pregnant women were less likely than non-pregnant women to have depression (7.3% vs 11.4%), alcohol abuse or dependence (2.8% vs 8.3%), or any mental disorder (19.2% vs 29.3%). There was no difference between pregnant and non-pregnant women in the prevalence of dysthymia, manic episodes, phobias, or drug abuse or dependence. Pregnancy per se was not associated with increased risk of the most prevalent mental disorders (although the risk of major depressive disorder appeared to increase postpartum).

Depressive disorders
Three systematic reviews reported the prevalence of antenatal depressive disorders, measured either by diagnostic interview and/or by validated self-screening tools. Chatillon et al estimated a rate of 5 to 15%. Bennett et al estimated rates as follows: first trimester 7.4% (95% CI 2.2 to 12.6), second trimester 12.8% (95% CI 10.7 to 14.8) and third trimester 12.0% (95% CI 7.4 to 16.7). Gavin et al estimated that during pregnancy up to 12.7% of women have an episode of major depression, up to 18.4% have either major or minor depression, and up to 14.5% of pregnant women have a new episode of major or minor depression.

Confidence intervals were wide for all estimates. Review authors explored possible reasons for the disparity between reported rates, but were unable to suggest an explanation. Differences in findings between the systematic reviews may relate to their population differences, as only one was clearly restricted to population-based studies. It was unclear whether women experience depression on a continued or intermittent basis throughout pregnancy, and moreover disease severity was not well documented.

Obsessive compulsive disorder (OCD)
A systematic review reported a mean prevalence of OCD in pregnancy of 1.64% (95% CI 1.23% to 2.2%). However there was huge variability in estimates
across the 12 relevant studies (from 0.20% to 29%). Comparison with ‘matched’ studies with non-pregnant controls suggested an increased risk in pregnant women (RR 1.45, 95% CI 1.07 to 1.96).

**Evidence on functional impact**
Mental health disorders can cause substantial disruption to daily functioning. However, NICE guidelines state that the nature and course of such disorders occurring in pregnancy does not substantially differ from such disorders at any other time, though they may necessitate more urgent intervention.92

A Norwegian population-based study 3* of sick leave during pregnancy reported that anxiety or depression, were responsible for the longest median duration of sick leave (20 weeks), but only 2% of women reported this as an indication for leave. The study authors suggested that this is probably an underestimate, as the questionnaire response rate was lower in this group.

**Summary of evidence**
Estimated rates for specific mental health disorders in pregnancy varied widely across studies. Evidence from population-based studies suggested that about 7% of women have depressive disorders in the first trimester, rising to 12-13% in the second and third trimesters. However, there was a high degree of uncertainty for all estimates. US survey data suggested that about 19% of women have any type of DSM-IV psychiatric disorder in pregnancy.

There was some suggestion of an increased rate of obsessive compulsive disorder in pregnancy, but the evidence did not appear robust.

Rates for the most prevalent mental health disorders in pregnant women are similar to, or lower than, rates in other women.

The symptoms and course of mental disorders in pregnancy are similar to those experienced by non-pregnant women, though they may require more urgent intervention. The functional impact of such disorders can be severe: anxiety or depression were responsible for longer sick leave (20 weeks) than any other health problem.
References

Appendix 1: Methods

Inclusion criteria

*Included:*
- Studies of the incidence of common effects and complications of pregnancy.
- Systematic reviews, population-based cohort and cross-sectional studies (in order of preference)

*Excluded:*
- Lower-level studies (e.g. retrospective, case-control) unless no data were available from studies with higher level of evidence.
- Unpublished and ongoing studies, studies without at least abstract in English

Review outcomes
The prevalence and manifestation of the following conditions in pregnancy:
1. Overall symptoms and indications for sick leave
2. Complications of pregnancy
3. Fatigue and sleep problems
4. Nausea and vomiting
5. Pelvic and back pain
6. Headaches and migraine
7. Urinary and bowel problems
8. Vaginal bleeding
9. Miscarriage
10. Ectopic pregnancy
11. Venous thrombosis
12. Pre-eclampsia and eclampsia
13. Pre-term birth
14. Cognitive disorders
15. Mental health disorders
16. Abdominal girth and mobility

Search
The search was designed in consultation with a Cochrane Collaboration information specialist. We searched the following sources:
- MEDLINE/PubMed
- The Cochrane Library
- CINAHL
- PsycINFO
- Web of Science
- TRIP
- EMBASE
- Google
- Reference lists of articles retrieved
We also made extensive use of the citation-linking tools on Medline and Web of Science.
The basic MEDLINE search was as follows. We added keywords (e.g. fatigue, nausea, vomiting, back pain) to search within the results for the outcomes of interest. The search was adapted for other databases:

1. Epidemiologic studies/
2. exp case control studies/
3. exp cohort studies/

**Study selection, data extraction and quality assessment**

Relevant studies were selected and data were extracted on their characteristics, risk of bias and findings of the included studies (see Appendix 2). The risk of bias assessment took into account to what extent studies met the following criteria:

**Reporting**
- methods described in sufficient detail
- findings clearly expressed, with measures of variability
- authors’ conclusions well-supported by evidence

**Study design**
- data-collection prospective

**Sample:**
- population-based
- applicable to a New Zealand setting
- appropriate control group used
- adequately powered to answer study question

**Outcome measures**
- valid measures used
- low risk of recall bias

**Completeness of data**
- high participation rate
- high follow-up rate

**For systematic reviews**
- rigorous search
- heterogeneity adequately addressed
- risk of bias in primary studies adequately addressed

2. Systematic review: Rate of antepartum VT per 100,000 person-years for pregnancies leading to live or stillbirth, and using a stringent definition of VT: Trimester 1: 46 (95% CI 31-70) Trimester 2: 58 (95% CI 41-83) Trimester 3: 182 (95% CI 150-221)

Rates were about 50% higher using a less stringent definition, and were more than twice as high using the least stringent definition. Authors described limitations of using less stringent definitions and/or only primary or only secondary data source. They noted that leg swelling and calf pain are common in pregnancy, without DVT

In the meta-analysis, there was high heterogeneity with antenatal incidence rates ranging from 53 to 144 per 100,000 years.

When meta-analysis was restricted to studies conducted after 2005 and those using
case-validation for VT, the pooled estimates for antenatal incidence of VT were similar to those calculated in the primary study.

The rate of VT peaked around the time of delivery and the first week of postpartum period (AR = 991 per 100,000 person years) after which the rates showed a graded decline throughout the remaining postpartum period

| Aegidius 2009 ¹⁰ Norway | • Cross-sectional population-based survey  
• Included all women who responded to questions on headache in a county-wide survey of residents aged over 20  
• 27,700/46,506 (60%) participation rate  
• Survey consisted of 2 questionnaires and a clinical examination  
• Non-pregnant | To evaluate the impact of pregnancy and parity on the 1-year headache prevalence in a large population-based study | Moderate risk of bias  
• Population based  
• 60% participation rate  
• Some risk of recall bias: participants were asked about headache during the last 12 months, rather than per trimester  
• Used validated self-report measures  
• Some potential for selection bias: participants were younger and had higher socioeconomic status than the non-responders  
• Comparison group were non-pregnant women rather than pre-pregnancy values in same women | Impact of pregnancy on the prevalence of headache and migraine  
(Used International Headache Society classifications)  
One-year headache prevalence: Both migraine and non-migrainous headache were less prevalent among nulliparous pregnant women than among non-pregnant women (One year prevalence: OR 0.5, 95% CI 0.4 to 0.7)  
The same trend was seen for other pregnant women but the difference was not significant (OR 0.8, 95% CI 0.7 to 1.0)  
There was no difference in headache prevalence during the first and second trimester compared with non-pregnant women but headache was significantly less prevalent in the third trimester. (OR 0.4, 95% CI 0.3 to 0.6) This was seen for all |

- Having antenatal care at study centre (n=8714)
  - Estimated as likely to include >97% local women

- Second trimester bleeds: 5%
- Median occurrence of first bleeding = 8 weeks (range 4-20)
- Median duration of bleeding: 2 days (range 1-12)

Among women with bleeding:
- 55% had one episode of short duration (i.e. bleeding for 1-3 days, lighter than normal period)
- 64% had no pain
- 31% of bleeders felt light pain
- 5% had moderate or severe pain for more than one day
- 19% of women with bleeding admitted to hospital, comprising 14% of women with first-trimester bleeding and 28% of women with second-trimester bleeding
- Hospitalisation was usually for <7 days for first trimester bleeding, <13 days for second trimester bleeding.

Unclear whether women experience depression on a continued or intermittent basis throughout pregnancy, or in subsequent pregnancies. Disease severity was not well documented.

Miscarriage rate = 12%
Clinical miscarriage constituted 12% of all pregnancies
One in four women had experienced a miscarriage by age 39 years.
Three or more miscarriages were
| **Boufous 2001** | **Australia** | Gotenborg in 1981 (n=656), 1991 (n=780) and 1982 (n=666)  
- Participants surveyed every 5 years  
- Data cross-checked with hospital records | To provide a more current assessment of the incidence of ectopic pregnancy in Australia by reporting rates for New South Wales between 1990 and 1998 | Moderate risk of bias  
- Retrospective analysis of registry data  
- Potential for data entry or coding errors  
- Unclear whether most recent data (from 1998) is applicable, as rates appear to be changing  
- Potential for double-counting, as all hospital discharges, transfers etc. recorded separately | Ectopic pregnancy (as per UCD-9 coding) | Annual incidence of ectopic pregnancy from 1990 to 1998:  
- Rate per 10,000 women declined from 11.1 (95% CI 10.5 to 11.7) to about 10 per 10,000 women in 1997-8  
- Incidence rate decreased from 17.4 per 1000 births (95% CI 16.5 to 18.3) in 1990-91 to 16 per 1000 births (95% CI 15.2 to 16.8) in 1997-8 (as per abstract) |
| **Buss 2006** | **Denmark** | Retrospective cohort study  
- Population data from hospital registries (New South Wales Inpatient Statistics collection)  
- Included 11,531 records of discharges, deaths or transfers for ectopic pregnancy | To measure rate of incident spontaneous abortion | Low risk of bias  
- Population sample  
- 68% participation  
- 80% follow up at 2 years | Spontaneous abortion rate as a proportion of all pregnancies intended to be carried to term (Spontaneous pregnancy loss up to 28 weeks) | Based on interview data:  
- 339 pregnancies (20.9%) of the pregnancies ended as spontaneous abortions  
- 1,247 pregnancies (76.9%) resulted in childbirth  
Based on registry data:  
- On the basis of the Hospital Discharge Register data, the spontaneous abortion rate reported by 7.4% of women. Miscarriage was not influenced by order of pregnancy.  
- Relatively low miscarriage rate may relate to high rate of legal abortion in Sweden (20%) |
Follow up by interview  
Data linkage to Hospital Discharge register to compare with interview findings  
Secondary analysis of data from study of HPV infection and cervical neoplasia

• Prospective cohort study  
• Included consecutive nulliparous women with singleton pregnancies in the third trimester (n=549), at a London teaching hospital  
• Excluded women with current or chronic past urinary tract problems

To investigate the effect of pregnancy and delivery on continence and to assess whether physical markers of collagen weakness can predict postpartum urinary and fecal incontinence (including incontinence of flatus).

Moderate risk of bias  
• Prospective, consecutive recruitment  
• London teaching hospital sample  
• Participation rate unclear  
• 100% follow-up  
• Characteristics similar to overall nulliparous population delivered over the same period (n=2211)  
• Ethnic distribution similar to rate in the whole institution  
• Generalisability unclear  
• Mean gestation at interview =37 weeks: potential recall bias

1. Urinary frequency, nocturia, urgency, and stress and urge incontinence.  

(self-reported voiding seven or more times per day or more than once every 2 hours; voiding on two or more occasions during the night; loss of urine on physical effort or coughing; loss of urine with a strong desire to void, respectively)

2. Faecal urgency and incontinence.  

(inability to defer defecation for longer than 5 minutes, incontinence of flatus and liquid and solid stool and soiling of underwear, respectively)

Severity of incontinence was was 16.3%.

More than 25% of the spontaneous abortions were only reported by the women, and this could not be explained by erroneously reported induced abortions, and may be early, non-hospitalized abortions.
assessed by the degree and frequency of incontinence, pad usage, and the effect on daily activities.

seven (13.7%) felt that it restricted their activities.

*Bowel symptoms during pregnancy:*

- Faecal urgency: 8.7%
- Flatus incontinence 6%
- Soiling of underwear 0.5%
- Liquid stool incontinence 0.9%
- Solid stool incontinence 0.2%
- Any incontinence 6%
- Urgency or incontinence 12.7%

Authors’ comment: None of these women complained voluntarily or sought medical help, which is not surprising because these symptoms are embarrassing and known to be underreported.

| Chappell 2013 SCOPE study NZ, Australia, UK, Ireland | codes on hospital database (Australia), or on a database of consecutive VT referrals (NZ) | To identify factors at 15 and 20 weeks’ gestation associated with a subsequent uncomplicated pregnancy. | Low risk of bias  
- Prospective, population based  
- 76% of potentially eligible women agreed to participate (3780/4961) | Uncomplicated pregnancy, (normotensive pregnancy delivered at >37 weeks’ gestation, resulting in a liveborn baby not small for gestational age, and the absence of any other significant pregnancy complications)  
Definition of complications:  
- Gestational hypertension  
- Pre-eclampsia  
- Gestational proteinuria  
- Gestational diabetes  
- Antepartum haemorrhage, placenta praevia, or placenta accreta  
- Placental abruption  
- Chronic hypertension (mild, diagnosed in pregnancy)  
Incidence of uncomplicated normotensive pregnancy:  
Overall: 61.3% (3452/5628)  
Australasia: 63.5%  
UK and Ireland: 58.6%  
Incidence of significant complication of pregnancy or baby small for dates: 39%  
Modifiable risk factors:  
Factors that reduced the likelihood of an uncomplicated pregnancy included increased body mass index (relative risk 0.74, 95% confidence intervals 0.65 to 0.84), misuse of drugs in the first trimester (0.90, 0.84 to 0.97), mean diastolic blood pressure (for each 5 mm Hg increase 0.92, 0.91 to 0.94), and mean systolic blood | trimester VT had a history of unprovoked VT.  
Management: Women were treated initially with either enoxaparin, dalteparin or intravenous unfractionated heparin at diagnosis. Forty-six (77%) received twice-daily weight-adjusted enoxaparin, whereas only nine (15%) received daily enoxaparin at diagnosis |
- Uncomplicated pregnancy compared with complicated pregnancy, by stepwise logistic regression

- Renal tract complications (e.g. pyelonephritis)
- Gastrointestinal tract or hepatic complications
- Respiratory complications (e.g. pneumonia)
- Other obstetric complications (e.g. obstetric cholestasis)
- Other medical complications (e.g. venous thromboembolism)
- Maternal death during pregnancy
- Small for gestational age infant (<10th customised birthweight centile)
- Spontaneous preterm birth
- Other fetal problems (including severe neonatal morbidity)
- Fetal anomalies
- Fetal death in utero ≥20/40 or neonatal death
- Fetal death in utero <20/40
- Miscarriage or abortion

| Chatillon 2010<sup>89</sup> Systematic review (in French) | Systematic review | Searched 2 databases | Included prevalence studies, epidemiological studies, clinical | To provide SR of data on prevalence, risk factors and adverse outcomes of antepartum depression | Moderate risk of bias | Antepartum depression | Prevalence of depression in pregnancy: 5-15%

The lower figure relates to major depression, as opposed to any depressive disorder.

Pregnancy is not protective against depression. |}

Beneficial factors were pre-pregnancy fruit intake at least three times daily (1.09, 1.01 to 1.18) and being in paid employment (per eight hours' increase 1.02, 1.01 to 1.04).

gestation scheduled to give birth at the study centre (n=2918)
• Measures at 17 weeks included insomnia, depression and pelvic girdle pain, using validated scales
• Multiple logistic regression used to identify factors associated with sick leave

4. Pelvic girdle pain
5. Anxiety or depression
6. Pregnancy complications

Indications for sick leave and median duration:
1. Fatigue or sleep problems: 34.7%, 8 weeks (cited as a factor in 49.3% of leave)
2. Nausea or vomiting: 23.1%, 16 weeks (cited as factor in 32.8% of leave)
3. Lower back pain: 17.7%, 10 weeks (cited as a factor in 25.1% of leave)
4. Pelvic girdle pain: 31.8%, 12 weeks (cited as a factor in 45.3% of leave)
5. Anxiety or depression: 2.1%, 20 weeks * (associated with longest duration of sick leave)
   (cited as a factor in 2.1% of leave)
6. Pregnancy complications: 9.2%, 13 weeks (cited as a factor in 13.1% of leave)

*May be an underestimate, as significantly lower response rate in women scoring high on depression scale at 17 weeks (70% versus 79%)

3rd trimester: 63%
All trimesters: 14%
Being on sick leave in all trimesters was strongly
associated with hyperemesis, exercising less than weekly, chronic pain before or during pregnancy, and infertility treatment (all $P < 0.001$), younger maternal age, and conflicts in the work place (both $P < 0.01$), multiparity, previous depression, insomnia and lower education (all $P < 0.05$).

A majority of women (60.1%) reported having had some adjustment of their work situation because of pregnancy. Most of the women who stayed in work throughout pregnancy without job adjustments responded that their work was not strenuous. (73.9%).

| Gartland 2010 | Cross-sectional analysis of baseline data from a prospective cohort study | To investigate women's general health and well-being in early pregnancy and examine the relationship between maternal age and women's physical and mental health. | Moderate risk of bias  
- Low participation of eligible women: rate not calculable, but estimated at 28-30%  
- Symptomatic women probably less likely to participate, so findings may be an underestimate | Physical and mental health of women in early pregnancy compared with age standardised population norms  
General health measured with SF-36 questionnaire  
Symptoms measured on 4 point scale: never | Pregnant women reported significantly higher scores for general health (i.e. usual non-pregnant health compared to others) but significantly lower scores for previous 4 weeks for nearly all SF-36 domains. Greatest negative physical impact was for physical and vitality scales |

miscarriage, (n=33), had termination (n=6), twins (n=5), treated for N&V (n=3), stillbirth (n=3) medical complications (n=4) ectopic (n=1), unco-operative (n=9), or lost to follow-up (n=8)  
- Large urban practice (n=14,500)

• Stopped (often abruptly) at mean 84 days (12 weeks) post LMP (range 44-213 days)  
• 91% of women had no symptoms after 16 weeks  
• 35% of women in paid employment (73/206) had time off work due to N&V: mean 62 hours; significantly correlated with severity of symptoms  
• Mean duration of symptoms: 56 hours (interquartile range 22-139); 41 days (interquartile range 28-56)  
• Nausea most commonly occurred between 6 am and midday, but could occur at any time of day.
Melbourne.  
(n=1535 enrolled, 1507 included in analysis)  
• Mean gestation 15 weeks (range 6–24)

Random sample of Finnish women aged 18-44 on population register (n=3000 invited, 2189 participated) for the reproductive life span of women in a population-based study. retrospective recall

By the age of 40 to 44 years, 90% of the women had been pregnant, and for only half had all pregnancies ended in a birth. The sequence of a miscarriage or miscarriages coming first and a birth or births coming later was more common than vice versa.

Henry 2007

Systematic review

- 3 databases searched, plus references, to May 2007
- Included studies in English, of healthy pregnant women which included a nonpregnant control group (n=14)
- Studies required to use an objective index of memory

To address how pregnancy affects memory

Moderate risk of bias

- Unclear how primary studies recruited intervention and control groups
- Quality of primary studies not reported
- Smallish overall sample (14 studies, 412 pregnant women, 386 controls)
- Groups appear fairly well matched demographically (age and years of education)
- Funnel plot showed no evidence of publication bias
- Significant and unexplained statistical heterogeneity for 3/7 outcomes

Measures of memory

(Definition of implicit vs explicit memory: “Whereas tests of explicit memory require deliberate recall of information from a specific learning episode, implicit memory refers to the unconscious accessing of previous experiences, in the absence of intentional recollection”.)

| Performance for pregnant vs non-pregnant women on measures of memory. |
|-----------------------------|-----------------------------|-----------------------------|
| Short term memory: -0.05 (SE 0.08) (3 studies, n=171) |
| Working memory: -0.16 (SE 0.08) (4 studies, n=211) |
| Free recall: -0.21 (SE 0.09) (8 studies, n=499) |
| Delayed free recall: -0.22 (SE0.06) (4 studies, n=228) |
| Recognition: 0.09 (SE 0.23) (2 studies, n=81) |
| Implicit memory: -0.03 (SE 0.12) (5 studies, n=260) |
| Subjective memory: -0.26 (SE 0.07) (7 studies, n=370) |
### As interpreted by study authors:
- "The results indicate that pregnant women are significantly impaired on some, but not all, measures of memory, and, specifically, memory measures that place relatively high demands on executive cognitive control may be selectively disrupted."
- "The magnitude of the deficits was invariably small, and thus the observed impairment may be regarded as relatively subtle"
- "The same specific deficits associated with pregnancy are also observed postpartum"

</thead>
</table>
| • Register-based study  
• Included female employees aged 20-45 years from Danish hospital (n=4852) and survey of women in the cohort who had been pregnant during their employment (n=773) |
| To describe risk indicators of long-term sick leave during pregnancy among hospital employees |
| Moderate risk of bias  
• 85% response rate among pregnant women  
• Generalizability to other populations unclear  
• Registry data: potential for recording errors |
| Risk factors for long term sick leave among pregnant women |
| • 31% of women were on sick leave for at least 10% of their scheduled work time during their latest pregnancy  
• 22% absent at least 20% of the time  
• Average sickness absence 6.1 days per month, = versus non-pregnant women 0.95 days per month  
• Sick leave was more frequent in late than in early gestation  
• Risk factors for long term sick leave were: part-time work, previous sickness absence not related to pregnancy, previous chronic back pain, much walking or standing, long working days, high work level, little practical support from supervisors and colleagues, low job control, much lifting, and night or shift work  
• Sick leave was unrelated to pregnancy |

Main reason for trouble sleeping in pregnancy was discomfort (in 67% women)

85
| Kristensen 31 2007 Norway | higher risk | The main objective was to examine whether job adjustment was associated with reduced absence | Moderate risk of bias  
- Population based  
- Overall response rate around 44%  
- Self-reported data | Absence from work  
Job adjustment  
(Job adjustment measured with the following questions: have your working conditions changed since you became pregnant, making it easier for you?” and: “if no, why have your working conditions remained unchanged?” with the options “not necessary” and four alternatives. Responses were collapsed into three categories: “not needed”, “needed and obtained” and “needed, not obtained”.) | Main risk factors:  
- For LBP: any history of LBP.  
- For LP: lower academic level, younger age, depression, a lower number of hours of sleep per day, and a higher BMI  
- For PGP: higher score for depression, higher BMI, and more advanced stage of pregnancy  
“Currently working “ was not associated with higher risk of LBP |

- Population-based cohort study  
- Invited to participate in connection with routine ultrasound offered to all pregnant women in Norway at 17-18 weeks’ gestation  
- Current study includes employed women in 1999-2005 cohort (n=28611)  
- Women completed questionnaires, at

- Sick leave  
50.7% of participants took one or more days of six leave in weeks 13-28 (=14.9% of all person-days)  
36.2% had more than 15 days of absence  

Relationship between absence from work and job adjustment  
Absence was strongly dependent on the pregnant woman’s own perception of the need for job adjustment. Among those who needed job adjustment, absence levels were lower when this was obtained.

</tbody>
</table>

Week 36:
• Pain with onset before pregnancy: 16%
• New onset pain: 47.3%
• The mean score for the worst pain in the previous week was rated at 6.5/10 on a VAS scale

There was a steady increase in pain up to week 18. Incidence increased sharply to week 22 then leveled off. Prevalence of new or ongoing pain at 24 weeks was 63.3% |

New-onset pain was usually sacral
Pain usually short-term: long-term pain was rare.
Pain intensity increased over
| Kvisvik 2011 | Norway | • Prospective population-based study  
• Included all pregnant women in catchment area of two hospitals in Norway (n=3125 invited, 2126 participated, 1618 completed 2 questionnaires)  
• Excluded women with high-risk pregnancies or known complications  
• Questionnaires administered at booking, in late pregnancy and postnatally | To describe prospectively and in detail the overall course of all headaches collectively and also of migraine during pregnancy and the puerperium. | Moderate risk of bias  
• Population sample  
• Prospective follow-up  
• Participation rate 68% of those eligible  
• 52% of those eligible completed questionnaires 1 and 2 | Prevalence of headaches and migraine during pregnancy (using International Headache Society criteria)  
Women with migraine kept headache diary. | New onset of headache in pregnancy versus freedom from pre-pregnancy headache:  
More women changed from having any headache before pregnancy to not having any headache during pregnancy (248/1,618=15%) than the other way around (101/1,618=6%) (p<0.001).  
Change in frequency of all headaches combined during pregnancy and puerperium:  
There was no significant difference (p=0.12) in the frequency of all headaches combined during pregnancy (n=1,122 reported headache) compared to before pregnancy (n=1,269 reported headache)  
There was a gradual decrease during pregnancy in the frequency of headaches and migraine in general.
### Characteristics of headaches during pregnancy and puerperium among migraineurs:

The intensity and duration of headaches were significantly reduced in pregnancy among migraineurs.

<table>

50% of cases resolved by 14 weeks 
90% of cases resolved by 22 weeks

In women with 2\text{nd} and 3\text{rd} trimester nausea, the intensity remained constant

For most women nausea lasted throughout the day

| Lok 2010 \(^6\) Hong Kong | • Prospective cohort study (n=190) | To investigate psychological morbidity after miscarriage in a prospective manner over a 1-year longitudinal course. | Moderate risk of bias
• Participation rate among miscarriage women: 75% (280/375)
• 32% of sample did not complete measures at all time points.
• Possible that study interview unintentionally had a therapeutic effect – though it was brief and focused on data collection
• Characteristics of non-participators and non-completers did not appear to differ in any way that would obviously cause high risk of bias
• Unclear whether sample was generalizable to NZ | • Psychological distress
• Depressive symptomatology (used validated self-report tools: General Health Questionnaire (GHQ-12, cut-off score 4) and Beck Depression Inventory (BDI, cut off score 12). Measured at baseline, 3, 6 and 12 months post miscarriage | • Among miscarriage women :
• 55% scored high on GHQ-12 immediately after miscarriage
• 25% scored high on GHQ-12 at 6 months
• 11% scored high on GHQ-12 at one year
• 27% scored high on BDI immediately after miscarriage
• 19% scored high on BDI at 3 months
• 9% scored high at one year
GHQ-12 scores significantly higher in miscarriage women (compared to controls) at all time points, though differences lessened over time |
Excluded women with history of psychiatric illness, or if follow-up likely to be problematic, e.g. due to immigration factors.

Ethnicity of participants not reported.

Population

Machonochie 2004 (63) UK

- Population-based cross-sectional survey
- Random sample from UK electoral roll (n>60,000)
- Targeted sample of women aged up to 55 who had ever been pregnant or ever attempted to achieve a pregnancy (n=10,828)
- Selected women likely to be aged 55 or under, based on name (e.g. Elsie versus Kylie!)
- Included in analysis 13,035 women, 30,661

To identify miscarriage rates among UK women who had ever been pregnant or ever attempted to achieve a pregnancy

Moderate risk of bias
- Response rate 49% to initial questionnaire
- 77% response from targeted sample (e.g. under 55 yrs)
- Retrospective data collection
- Risk of recall bias

Miscarriage: Spontaneous pregnancy loss <24 weeks gestation

Miscarriage rate: 11.5% of women, 12.7% of reported pregnancies.

BDI scores significantly higher in miscarrying women at 3 and 6 months (with differences lessening over time), but comparable at one year.

| Malmqvist 2012 49 Norway | X-sectional Survey | Population based | Included Norwegian-speaking women with singleton pregnancy of at least 12 weeks | To investigate the cumulative prevalence of low back pain (LBP), pelvic pain (PP), and lumbopelvic pain during pregnancy, | Moderate risk of bias | Retrospective data collection (post delivery) | 58% participation of eligible women | Sample appeared | Pain and disability associated with pelvic and lower back pain in current and previous pregnancies | Incidence of moderate or severe pain: At 5 months: | 3.1% had lumbar pain | 13.2% had pelvic pain | 6.8% had combined pain |}

Thromboembolism:
Authors state “Even although both air travel and pregnancy each increase the risk for thromboembolism, the actual effect of air travel on the risk of thromboembolism in pregnancy is uncertain”.

Authors conclude: “The paucity of data on air travel and pregnancy outcomes makes it impossible to provide evidence-based answers from the limited information available. The studies that would either validate or refute the safety of air travel in pregnant passengers, flight attendants and aviators is (sic) inadequate and will remain so until additional studies have been undertaken”.

Pain and disability associated with pelvic and lower back pain in current and previous pregnancies (Pain measured as mild/mod/severe. Function measured with Oswestry.

from National Epidemiologic survey 2001-2
• Included women aged 18-44, either currently pregnant (n=451) or not (n=10,544)
• Data collected by face-to-face interview

• Population based
Disorder and Associated Disabilities Interview Schedule-DSM-IV version)

Pregnant women were less likely than non-pregnant women to have depression (7.3% vs 11.4%), alcohol abuse or dependence (2.8% vs 8.3%), or any mental disorder (19.2% vs 29.3%)

Multiple linear regression analyses demonstrated that pregnant and non-pregnant women had higher mental component scores than past-year pregnant women.

There was no difference between pregnant and non-pregnant women in the prevalence of dysthymia, manic episodes, phobias, or drug abuse/dependence

North 2011 International, including NZ (SCOPE)*
• Prospective international cohort study
• Included a New-Zealand cohort
• Included healthy nulliparous women with singleton pregnancy (n=3572) at five centres 2004-8

To develop a predictive model for preeclampsia based on clinical risk factors for nulliparous women and to identify a subgroup at increased risk for whom specialist referral might be indicated

Low risk of bias
• Prospective
• Large multicentre sample
• 76% participation rate (3780/4961)
• Data on pregnancy outcome available for 99% of sample

Any pre-eclampsia
Pre-term pre-eclampsia
(Pre-eclampsia was defined as systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg, or both, on at least two occasions four hours apart after 20 weeks’ gestation with either proteinuria or any multisystem complication of pre-eclampsia (e.g. acute renal insufficiency).

Prevalence of preterm pre-eclampsia in healthy nulliparous women: 1.3%
• Prevalence of any preeclampsia: 5.3%
• Pre-eclampsia developed at a mean of 36.9 (SD 3.3) weeks’ gestation

Clinical risk factors at 14-16 weeks’ gestation were age, mean arterial blood pressure,
| Parazzini 2013<sup>75</sup> Italy | • Retrospective cohort study  
• Utilised 1996-2010 data from Lombardy Region Database  
• Included women aged 15-50 (n=1,777,011 pregnancies and 17,028 cases of ectopic pregnancy)  
• Abstract only available (full text currently embargoed) | To supply data on time trends for the incidence of ectopic pregnancies in Southern European populations | Moderate risk of bias  
• Retrospective analysis of registry data  
• Potential for data entry or coding errors | Ectopic pregnancy |

| Persson 2006; Daniellson 2012<sup>32,33</sup> | • Swedish National Public Health Reports | To monitor and analyse the development of health in various populations | Moderate risk of bias  
• Retrospective data  
• Potential for data coding | Pregnancy morbidity (and other health indicators) | • A third of women are treated in hospital at some point during pregnancy |
| **Sweden** | • Based on Swedish National Health Registers | groups of the population. By doing this the public health reports form a basis for evaluation and improvements of health policies | errors | • Absence from work due to illness is very common among women in the final stages of pregnancy.  
• Backaches are the most frequent cause  
• Other health problems such as difficulty sleeping, urinary incontinence and gastrointestinal complaints are also common. |

| **Piccardi 2013 Italy** | • Case report  
• Case is a female air force pilot who underwent a 2-D Mental Rotation Task in the second trimester of pregnancy, post-partum and one year after delivery  
• Outcomes compared with two non-pregnant groups of women, with and without flying experience | To investigate the ability of a female ItAF pilot to mentally rotate a stimulus (in terms of both accuracy and speed) during pregnancy and 1 yr after delivery. | Very high risk of bias  
• Single case  
• No pre-pregnancy measures for comparison:  
• Conclusions are based on assumption: “We cannot infer how the subject would have performed on the MRT before pregnancy, but we can assume that her performance would have been similar to that of other female pilots”  
• Poor reporting - authors emphasize differences between groups even where they were not statistically significant | Mental rotation ability  
(Each subject had to indicate which figure out of five alternatives corresponded with the target figure rotated up to 180°. The task included 20 subsequent stimuli and the score ranged from 0 (no correct answer) to 20 (all correct)) | • The subject performed the task within one SD below the mean for female pilots, without significant difference between pregnancy, post-partum or one year after delivery (though her performance was improved at one year post-delivery)  
• Performance during pregnancy was significantly better than non-pilots but worse than pilots. At one year post delivery, performance was not significantly different from the pilot group.  
• During pregnancy, the subject’s response time was significantly slower than with pilots and significantly faster than non-pilots. |
One year after delivery, her performance was still better than the non-pilot group and was almost the same as the pilot group. 

**Authors comment:** In this case, visuospatial ability requiring effortful processing underwent variations during pregnancy and postpartum. Further studies are needed in order to confirm our observations in a wider population.

<tr>
<td>- Systematic review</td>
</tr>
<tr>
<td>- Includes 12 studies of DVT in pregnancy or puerperium</td>
</tr>
<tr>
<td>- Searched MEDLINE 1966-1998; also searched reference lists</td>
</tr>
</tbody>
</table>

**To answer two questions about DVT during pregnancy and the puerperium:**

1) In which leg is there a higher incidence of disease?
2) When is DVT likely to present during pregnancy or the puerperium?

**Moderate risk of bias**

- Only searched one database
- Unclear whether age of studies (1969-97) may reduce applicability
- 80% of DVTs diagnosed using “objective testing” (e.g., imaging)
- Sensitivity analysis conducted excluding studies only using clinical diagnosis

**Characteristics of vein thrombosis (DVT) in pregnancy:**

- Which leg and when it occurred (As diagnosed in primary studies)

**Of DVTs occurring in pregnancy:**

- 22% occurred in the first trimester (95% CI 17.4 to 27.3)
- 34% occurred in the second trimester (95% CI 28.1 to 39.8)
- 48% occurred in the third trimester (95% CI 39.2 to 56.2)

Findings were similar when studies using clinical examination alone were excluded. DVT most commonly occurred in the left leg.

Risk in the puerperium was higher than antepartum.
| Robinson 2006 | Norway | Population-based survey, included all women in 2 municipalities in Norway who responded to postal questionnaire and who had a prior delivery (n=1187) | To estimate the prevalence of PGP according to pain location. An additional aim was to study the impact on function, the use of crutches, and waking up at night, according to location of pain | Moderate risk of bias | Pelvic girdle pain: prevalence and functional effects | Prevalence of pelvic girdle pain (PGP) in last pregnancy: 46% | Use of crutches to manage PGP: 7% of pregnant women; 16% of women with PGP | Waking up at night with PGP: 15% of all pregnant women; 33% of women with PGP | Sick leave: 67% of all postpartum women sick-listed during pregnancy, of these 41% were sick-listed due to PGP | Authors’ note: The observation that 7% of all pregnant women used crutches because of self-reported PGP demonstrates that this condition causes severe functional disability for many pregnant women. In this group, false classification of PGP is unlikely since women with gynecological, urological, and lumbar pain are not likely to use crutches |
| Russell 2013 | Systematic review | Systematic review, searched 4 databases and references to August 2012, included English-language papers | To provide an estimate of OCD prevalence in pregnant and postpartum women | Moderate risk of bias | Prevalence of OCD (diagnosed using structured clinical interview) | Prevalence of OCD in pregnancy: 1.64% (95% CI 1.23% to 2.20%): High heterogeneity (I² = 81%) | | | | |

### Treatment of Pelvic Girdle Pain

**For determining incidence of pregnancy-related pain,** included prospective studies of pelvic pain in which diagnosis confirmed by a pain history and, preferably by a clinical examination. (n=4)

**Selected studies all prospective and population based**
- Review reports point prevalence rather than prevalence throughout pregnancy
- Authors’ conclusions appear to be well-supported by only one of the four selected studies.

**For the purpose of this review, overall prevalence rates extracted from primary studies (where reported)**

#### Ostgaard 1990
- Point prevalence of low back pain and sacroiliac pain at week 30: about 32%
- Sacroiliac pain alone at week 30: 19%
- Point prevalence at 12 weeks: 22%
- 9-month prevalence of either pain: 49%, of whom 22% had ongoing back pain when they became pregnant
- Authors noted "Physically heavy work, lifting, twisting, forward bending, poor work satisfaction, postwork fatigue, inability to take rest breaks and constrained working postures were vocational factors associated with increased complaints of back pain during pregnancy"

#### Larsen 1999
- Incidence of pelvic pain in pregnancy (sic): 14% [Vleeming states point prevalence of 16%]

#### Berg 1988

---

112
Incidence of low back pain in pregnancy = 49%, severe in 9% of cases. 9% of women gave up work due to low back pain.

Vleeming et al did not report cumulative incidence, and concluded that point prevalence of pregnant women suffering from PGP is about 20%.

Weiss 2004

<tbody>
<tr>
<td>• 14% had any bleeding</td>
</tr>
<tr>
<td>• 13% had light bleeding</td>
</tr>
<tr>
<td>• 1% had heavy bleeding</td>
</tr>
</tbody>
</table>

Incidence of pregnancy loss between 14 and 24 weeks: 0.5%

Risk of fetal loss was proportional to amount of vaginal bleeding.

 Compared with the control group (no bleeding), women with light and heavy vaginal bleeding were significantly more likely to have a spontaneous loss before 24 weeks of gestation (OR 2.5 and 4.2 respectively).

Authors’ comment:
Women with symptoms of a threatened abortion after 10 weeks of gestation are extremely likely to reach viability. The likelihood of maintaining a viable pregnancy in women with threatened abortion was 98% through 24 weeks of gestation.

|   • An Australian study of 593
| Yang 2004 | **USA** | • Prospective cohort study  
• Included pregnant women at 24-29 weeks gestation (n=2829, 2820 had complete data and included in analysis)  
• Participants recruited from university medical centre and county  
To evaluate association between self-reported vaginal bleeding and preterm birth | Moderate risk of bias  
• Described as moderately high-risk sample  
• First trimester bleeding assessed retrospectively at 24-31 weeks  
• Authors acknowledge that “bleeding episode” was poorly defined so some characteristics may have been misclassified | Bleeding in pregnancy ongoing at 24-29 weeks (self-reported):  
(Light spotting; Heavy bleeding (required a pad or soaked underwear))  
Pre-term birth | Volunteers with N&V in early pregnancy described its impact on employment (see entry above for Smith 2000)  
• In a prospective Swedish survey (n=4041) pregnant women who took sick leave due to NVP took on average 13 days of leave, comprising 28% of all sick leave taken up to week 28 (Kallen 2003).  
• A Canadian cross-sectional observational study of pregnancy women with NVP (n=139) found that it diminished work productivity, with increased severity of symptoms exacerbating the decline. |
| health department: described as a moderately high-risk population |  |  |  | • Women with initial bleeding in second trimester had less total blood loss than women with initial bleeding in first semester |
